QuakeWatch Review 2

This report is based on the real QuakeWatch source tree, the project documentation, and verification logs already present in the workspace. It explicitly distinguishes confirmed evidence from blocked live validation that requires an active ArangoDB instance.

Project: QuakeWatch | Stack: Django, Python, ArangoDB, HTML/CSS/JS, Bootstrap | Source: README.md, docs/ARCHITECTURE.md, docs/AQL_QUERIES.md, submission_artifacts/06_aql_queries/selected_15_queries.md.

Database evidence: the project is deliberately designed around ArangoDB as the sole stateful database. The baseline AQL-catalogue log confirms schema creation, index creation, view creation, and query optimizer choices for 47 named queries. The current Windows workspace however does not expose a live ArangoDB service, so record counts, transaction execution, and export creation remain blocked and must be re-run against a verified local database.

Query evidence: multiple query families exist for alerts, analytics, event lookups, geo search, revision inspection, and operations. The catalogue includes 53 named queries; the project also has a selected 15-query set ready for Review 2 presentation. Historical output shows query execution status and index usage across a seeded benchmark database.

Testing evidence: Phase 0 baseline results recorded 601 passed, 0 failed, 0 errors, and 93.96% coverage. Browser/accessibility checks also passed in the historical baseline. These results are valid as historical evidence but not as a current live verification claim for the present working copy, which does not presently have a running ArangoDB listener.

Outcome: the project is validly documented and the documentation/evidence set is sufficient for Review 2 source analysis; the remaining live-environment steps are blocked by the absence of a reachable ArangoDB service and must be executed in a separate, safely managed local environment.
